Aims of the Talk

A <u>VERY</u> short (and incomplete) introduction to:

- Sequencing technologies
- Sequencing approaches/strategies
- Technical/computational challenges
- Data analysis pipelines
- Genome anatomy
- Genome comparison

Genomics Timeline

- ▶ 1975 Sanger sequencing
- 1995 1st genome sequenced: Haemophilus influenzae
- 1996 1st eukaryote sequenced: Saccharomyces cerevisiae
- 1996 1st archaeon sequenced: Metanococcus janneschii (sampled @ 2600m of depth in the Pacific Ocean)
- 1998 1st metazoan sequenced: Caenorhabditis elegans
- 1999 Drosophila melanogaster genome sequenced
- > 2000 1st draft of the human genome completed
- ▶ 2001 Publication of the human genome
- > 2002 Mus musculus sequenced
- > 2004 Rattus norvegicus sequenced
- ▶ 2005 Chimpanzee genome sequenced
- ▶ 2008 1KGP starts
- > 2009 Genome 10K project established
- 2011 i5k Project established
- > 2013 1st GIGA workshop
- >2017 Vertebrate Genome Project started
- > 2018 Earth BioGenome project launched
- ▶ 2020 ERGA consortium

Sequencing Technologies: Overview

https://flxlexblog.wordpress.com/2016/07/08/developments-in-high-throughput-sequencing-july-2016-edition/

Sequencing Modes Short reads

• Single-end sequencing

• Paired-end sequencing

Paired-End Reads

Paired-end sequencing enables both ends of the DNA fragment to be sequenced. Because the distance between each paired read is known, alignment algorithms can use this information to map the reads over repetitive regions more precisely. This results in much better alignment of the reads, especially across difficult-to-sequence, repetitive regions of the genome.

Long Reads

MPS Workflow

Assembly Stats: N50, N90

- N50 statistic defines assembly quality in terms of contiguity. Given a set of contigs, the N50 is defined as the sequence length of the shortest contig at 50% of the total genome length. It can be thought of as the point of half of the mass of the distribution.
- N50 can be described as a weighted median statistic such that 50% of the entire assembly is contained in contigs or scaffolds equal to or larger than this value.
- The N90 statistic is the length for which the collection of all contigs of that length or longer contains at least 90% of the sum of the lengths of all contigs, and for which the collection of all contigs of that length or shorter contains at least 10% of the sum of the lengths of all contigs.
- Example:

<pre># Scaffolds</pre>	Gsize	N50	N50_scaffold#	N90	N90_scaffold#
301516	2021935850	12068	46019	2414	170482

In this case, 50% of the assembly is represented by 46,019 scaffolds with length ≥ 12068bp. 90% of the assembly is represented by 170,482 scaffolds with length ≥ 2414bp.

Assembly Stats: method comparison

Comparison of assembly size vs estimated genome size

Assessing genome assembly and annotation completeness with Benchmarking Universal Single-Copy Orthologs

About BUSCO

BUSCO v3 provides quantitative measures for the assessment of genome assembly, gene set, and transcriptome completeness, based on evolutionarilyinformed expectations of gene content from near-universal single-copy orthologs selected from OrthoDB v9.

BUSCO assessments are implemented in open-source software, with a large selection of lineage-specific sets of Benchmarking Universal Single-Copy Orthologs. These conserved orthologs are ideal candidates for large-scale phylogenomics studies, and the annotated BUSCO gene models built during genome assessments provide a comprehensive gene predictor training set for use as part of genome annotation pipelines.

Datasets

Protists sets

Metazoa sets

Fungi sets

Plants set

BUSCO results

Summarazing, three questions:

1) How much of the genome is really sequenced

3) Genome contiguity

Annotation

1. Sequence Similarity:

- Nucleotide sequence (e.g. blastn)
- Amino acid sequence (e.g. blastp)
- HMM profile (es. hmmer)
- Signatures (es. InterProScan)

2. Assignment of GO Terms.

Gene ontology (GO) is a major bioinformatics initiative to unify the representation of gene and gene product attributes across all species.

The project aims to:

- 1) maintain and develop its controlled vocabulary of gene and gene product attributes;
- 2) annotate genes and gene products, and assimilate and disseminate annotation data;
- 3) provide tools for easy access to all aspects of the data provided by the project, and to enable functional interpretation of experimental data using the GO, for example via enrichment analysis.

In computer science and information science, an ontology encompasses a representation, formal naming and definition of the categories, properties and relations between the concepts, data and entities that substantiate one, many or all domains.

-Wikipedia

Annotation

The ontology covers three domains:

- Cellular component, the parts of a cell or its extracellular environment;
- **Molecular function**, the elemental activities of a gene product at the molecular level, such as binding or catalysis;
- **Biological process**, operations or sets of molecular events with a defined beginning and end, pertinent to the functioning of integrated living units: cells, tissues, organs, and organisms.

Each GO term within the ontology has a term name, which may be a word or string of words; a unique alphanumeric identifier; a definition with cited sources; and a namespace indicating the domain to which it belongs.

Terms may also have synonyms, which are classed as being exactly equivalent to the term name, broader, narrower, or related; references to equivalent concepts in other databases; and comments on term meaning or usage.

The GO ontology is structured as a directed acyclic graph, and each term has defined relationships to one or more other terms in the same domain, and sometimes to other domains.

The GO vocabulary is designed to be species-neutral, and includes terms applicable to prokaryotes and eukaryotes, single and multicellular organisms.

Why Sequencing Genomes?

Gain better understanding of biology

Gain knowledge about genetic variation

Allow the comparisons between taxa (understand evolution)

- How much/How genes vary across taxa?
- How much/How genome architecture changes?
- How much/How gene content changes?
- Reconstruct phylogenetic relationships and evolution of taxa
- Reconstruct the evolutionary history of a species
- Biomedical/veterinary applications

Forensic applications

Some MPS Applications

FUNCTIONAL GENOMICS

Understanding the function of genes and other genetic elements in a genome

COMPARATIVE GENOMICS

Comparing genomes of different organisms

POPULATION GENOMICS

Large-scale comparison of DNA sequences in populations

METAGENOMICS

Study of genetic material directly from environmental samples

CONSERVATION GENOMICS

Application of genomic analysis to the preservation of the viability of populations and the biodiversity of living organisms

Functional Genomics

Use of the vast wealth of data given by genomic and transcriptomic projects to describe gene functions and interactions.

Focuses on the dynamic aspects such as gene transcription, translation, regulation of gene expression, and protein–protein interactions, as opposed to the static aspects of the genomic information such as DNA sequence or structures.

Attempts to answer questions about the function of genetic elemets at the levels of genes, RNA transcripts, and protein products.

A key characteristic of functional genomics studies is their genome-wide approach to these questions, generally involving high-throughput methods rather than a more traditional "gene-by-gene" approach.

Abstract

Males and females share the same genome, thus, phenotypic divergence requires differential gene expression and sexspecific regulation. Accordingly, the analysis of expression patterns is pivotal to the understanding of sex determination mechanisms. Many bivalves are stable gonochoric species, but the mechanism of gonad sexualization and the genes involved are still unknown. Moreover, during the period of sexual rest, a gonad is not present and sex cannot be determined. A mechanism associated with germ line differentiation in some bivalves, including the Manila clam Ruditapes philippinarum, is the doubly uniparental inheritance (DUI) of mitochondria, a variation of strict maternal inheritance. Two mitochondrial lineages are present, one transmitted through eggs and the other through sperm, as well as a motherdependent sex bias of the progeny. We produced a de novo annotation of 17,186 transcripts from R. philippinarum and compared the transcriptomes of males and females and identified 1,575 genes with strong sex-specific expression and 166 sex-specific single nucleotide polymorphisms, obtaining preliminary information about genes that could be involved in sex determination. Then we compared the transcriptomes between a family producing predominantly females and a family producing predominantly males to identify candidate genes involved in regulation of sex-specific aspects of DUI system, finding a relationship between sex bias and differential expression of several ubiquitination genes. In mammalian embryos, sperm mitochondria are degraded by ubiquitination. A modification of this mechanism is hypothesized to be responsible for the retention of sperm mitochondria in male embryos of DUI species. Ubiquitination can additionally regulate gene expression, playing a role in sex determination of several animals. These data enable us to develop a model that incorporates both the DUI literature and our new findings.

Key words: Ruditapes philippinarum, de novo, transcriptome, doubly uniparental inheritance, sex bias, sex determination.

Abstract

Comparative genomics has become a central tool for evolutionary biology, and a better knowledge of understudied taxa represents the foundation for future work. In this study, we characterized the transcriptome of male and female mature gonads in the European clam *Ruditapes decussatus*, compared with that in the Manila clam *Ruditapes philippinarum* providing, for the first time in bivalves, information about transcription dynamics and sequence evolution of sex-biased genes. In both the species, we found a relatively low number of sex-biased genes (1,284, corresponding to 41.3% of the orthologous genes between the two species), probably due to the absence of sexual dimorphism, and the transcriptional bias is maintained in only 33% of the orthologs. The *dN/dS* is generally low, indicating purifying selection, with genes where the female-biased transcription is maintained between the two species showing a significantly higher *dN/dS*. Genes involved in embryo development, cell proliferation, and maintenance of genome stability show a faster sequence evolution. Finally, we report a lack of clear correlation between transcription level and evolutionary rate in these species, in contrast with studies that reported a negative correlation. We discuss such discrepancy and call into question some methodological approaches and rationales generally used in this type of comparative studies.

Key words: RNA-Seq, transcription level, evolutionary rate, gametogenesis, embryo development, E-R correlation.

Epigenomics: Bisulfite Sequencing

ChIP-Seq

Comparative Genomics

Compares the genomic features (DNA sequence, genes, gene order, regulatory sequences, and other genomic structural landmarks) of different organisms.

Whole or large parts of genomes resulting from genome projects are compared to study basic biological similarities and differences as well as evolutionary relationships between organisms.

The major principle of comparative genomics is that common features of two organisms will often be encoded within the DNA that is evolutionarily conserved between them.

Comparative genomic approaches start with making some form of alignment of genome sequences and looking for orthologous sequences (sequences that share a common ancestry) in the aligned genomes and checking to what extent those sequences are conserved. Based on these, genome and molecular evolution are inferred and this may in turn be put in the context of, for example, phenotypic evolution or population genetics.

Genome

(from Wikipedia, the free encyclopedia)

In the fields of <u>molecular biology</u> and <u>genetics</u>, a genome is all genetic information of an organism.^[1] It consists of nucleotide sequences of <u>DNA</u> (or <u>RNA</u> in <u>RNA</u> <u>viruses</u>). The genome includes both the <u>genes</u> (the <u>coding regions</u>) and the <u>noncoding DNA</u>, as well as <u>mitochondrial DNA</u> and <u>chloroplast DNA</u>.

therefore the genome is plenty of genes...

Abstract

The function of most proteins is not determined experimentally, but is extrapolated from homologs. According to the "ortholog conjecture", or standard model of phylogenomics, protein function changes rapidly after duplication, leading to paralogs with different functions, while orthologs retain the ancestral function. We report here that a comparison of experimentally supported functional annotations among homologs from 13 genomes mostly supports this model. We show that to analyze GO annotation effectively, several confounding factors need to be controlled: authorship bias, variation of GO term frequency among species, variation of background similarity among species pairs, and propagated annotations bias. After controlling for these biases, we observe that orthologs have generally more similar functional annotations than paralogs. This is especially strong for sub-cellular localization. We observe only a weak decrease in functional similarity with increasing sequence divergence. These findings hold over a large diversity of species; notably orthologs from model organisms such as *E. coli*, yeast or mouse have conserved function with human proteins.
